ABSTRACT

The pressure and phase distribution of sound in a fast fluid medium underlying a tapered fluid medium was modeled using a Green's function approach. The model predicted well defined beams in the bottom, with apparent interference effects strongly evident for cases at a distance from the wedge interface. The effects of attenuation on the patterns were studied. A simple expression for determining the beam depression angle as a function the wedge angle, the sound speed ratio, and the density ratio was derived. Comparisons with laboratory measurements were made.

I. INTRODUCTION

The problem of radiation behavior in a wedge-shaped medium overlying a bottom possessing a greater speed of sound has been investigated both optically and acoustically. In 1971, Tien and Martin (Ref. 1) deposited a thin, tapered, dielectric film on a substrate having a higher refractive index, and observed the behavior of a laser beam coupled into the film. Perfect reflection at the film-substrate interface was observed until the changing angle of incidence decreased below the critical angle for continued mode propagation. For angles of incidence below critical, the light was converted into radiation modes in the substrate.

A concurrent analysis of the acoustic problem was done by Kuznetsov (Ref. 2). Kuznetsov developed a theory, based on normal-modes, that predicted the following for sound propagating within a wedge-shaped medium overlying a half-space with a higher sound speed:

1. As the sound approached the vertex of the wedge, it would continue to be totally reflected until the angle of incidence decreased to the limiting angle of total reflection.
2. Sound incident at less than the limiting angle of total reflection would be totally refracted into the underlying half-space. This refraction occurs within the region from the wedge apex to the point where the limiting angle was attained.

3. Within the half-space, the acoustic energy would be propagated as a well defined beam with the maximum pressure amplitude occurring at an angle of depression from the wedge interface within the range β to 2β , where β is the wedge angle.

Kuznetsov also performed a series of experiments that supported his theory.

Subsequent optical experiments by Tien, Smolinsky, and Martin (Ref. 3) demonstrated the formation of a well-defined beam within the substrate. The accompanying theoretical discussion predicted conflicting behavior. Ray-optics predicted refraction into the substrate after the cutoff distance (the point where refraction begins) and wave theory predicted complete refraction into the substrate before the cutoff point. Sigelman, et. al. (Ref. 4) both predicted and observed a well columnated beam in a water-aluminum wedge system, but the observed beam was much broader than predicted. Also, the pressure maxima for the columnated beam occurred at approximately 11° for a wedge angle of 1.3° , well outside the limit predicted by Kuznetsov.

The primary objective of this theoretical development is to produce a simple, fast computer model to predict the pressure and phase distribution of the columnated sound beam in the fast substrate. The pressure and phase distribution along the wedge interface calculated by Kawamura (Ref. 5) will be used as input to the substrate model, and will specifically be used as the boundary conditions for a Green's function analysis. To remove explicit frequency dependence, all relevant distances will be normalized to the distance measured from the apex along the wedge interface at which the critical reflection angle is first exceeded; this dump

distance is referred to as the dump distance X . Integration over the wedge interface will be truncated at distances sufficient to encompass only selected modes of interest. Results will be analyzed for trends and compared with existing measured data.

II. THEORY

Pressure and phase distributions along the bottom of a wedge-shaped medium are obtained using an adaptation of the method of images as prescribed in Ref. 5. The source may be set at either finite or infinite distance, but must be maintained sufficiently far from the wedge boundaries to ensure that impinging waves are essentially locally planar. The following theoretical discussion uses the above pressure and phase distribution as initial conditions, and calculates the pressure and phase distribution in the fast bottom by utilizing the Green's function (Ref. 6).

Figure II-1 illustrates the geometry of the problem. The horizontal x-axis and the vertical z-axis have their point of origin at the wedge apex, with the positive x-axis forming the interface between the wedge and fast bottom. The wedge angle is designated β and the angle specifying the sound source location is δ . X is the first mode dumping distance, and is a distance determined as follows:

$$\theta_c = \arccos (C_2 / C_1) \quad (\text{II-1a})$$

$$D_0 = C_1 / \{ 4 \cdot f \cdot \sin(\theta_c) \} \quad (\text{II-1b})$$

$$X = D_0 / \sin(\beta) \quad (\text{II-1c})$$

Figure II-1 Wedge Problem Geometry

where

C_1 = sound speed in the wedge

C_2 = sound speed in the bottom

f = frequency

and D_0 = lowest mode cut-off depth.

To make the problem frequency independent, all distances were normalized to X by defining

$$\xi = x / X \quad (\text{II-2a})$$

$$\xi' = x' / X \quad (\text{II-2b})$$

$$\eta = z / X \quad (\text{II-2c})$$

The variable x' is identical to x , and ξ' is identical to ξ . The prime designation is required for dummy variables of integration in the Green's function development to follow.

Pressure along the wedge bottom is then given by

$$p(\xi, \eta=0, t) = P(\xi) \exp \{ i[\omega t + L(\xi)] \} \quad (\text{II-3})$$

where $P(\xi)$ is the pressure amplitude along the wedge bottom and $L(\xi)$ is the phase along the wedge bottom. Pressure in the bottom, away from the boundary, is then given by Ref. 7,

$$\begin{aligned} p(\vec{r}, t) &= \exp[i\omega t] \frac{1}{4\pi} \int_0^\infty P(\xi') \left. \frac{\partial G}{\partial z'} \right|_{z'=0} X d\xi' \\ &\equiv \exp [i\omega t] R(\vec{r}) \end{aligned} \quad (\text{II-4})$$

where G is the appropriate Green's function. The z' coordinate is identical to the z coordinate and $\vec{r} = (\vec{x}^2 + \vec{z}^2)^{1/2}$. The appropriate Green's function, for a line source in cylindrical geometry is

$$G(\vec{r}, \vec{r}') = i\pi H_0^{(2)}(k_2 |\vec{r} - \vec{r}'|) \quad (\text{II-5})$$

where k_2 is the propagation vector in the bottom and $\vec{r} = [(\vec{x}')^2 + (\vec{z}')^2]^{1/2}$.

Differentiation of the Green's function yields (Ref. 7)

$$\frac{\partial G}{\partial z'} = i\pi H_1^{(2)}(k_2 |\vec{r} - \vec{r}'|) \frac{k_2(z - z')}{|\vec{r} - \vec{r}'|} \quad (\text{II-6})$$

where $k_2 |\vec{r} - \vec{r}'| \gg 2\pi$ and $H_0^{(2)}$, $H_1^{(2)}$ are zero and first order Bessel functions of the third kind (Hankel functions) respectively. Using equations (II-2a,b,c) at $z' = 0$ the expression $|\vec{r} - \vec{r}'|$ may be rewritten as

$$|\vec{r} - \vec{r}'| = X [(\xi - \xi')^2 + \eta^2]^{1/2} \quad (\text{II-7})$$

Substituting (II-7) into equation (II-6), and evaluating $\frac{\partial G}{\partial z'}$ at $z' = 0$ yields

$$\left. \frac{\partial G}{\partial z'} \right|_{z'=0} = \frac{\pi \left(\frac{2}{\pi k_2} \right)^{1/2} \exp\left(\frac{i\pi}{4}\right) \exp\{-ik_2 X [(\xi - \xi')^2 + \eta^2]^{1/2}\} k_2 \eta X}{X^{3/2} [(\xi - \xi')^2 + \eta^2]^{3/4}} \quad (\text{II-8})$$

Combining equations (II-8) and (II-4) yields a time independent expression for amplitude and phase, $R(\vec{r})$

$$R(\vec{r}) = \frac{\eta}{4} \exp\left(\frac{i\pi}{4}\right) \left(\frac{2k_2 X}{\pi}\right)^{1/2} \int_0^\infty \frac{P(\xi') \exp\{i[L(\xi') - k_2 X [(\xi - \xi')^2 + \eta^2]^{1/2}]\} d\xi'}{[(\xi - \xi')^2 + \eta^2]^{3/4}} \quad (\text{II-9})$$

Equation (II-9) is the basic equation used for the calculation of phase and amplitude in the bottom.

III. DEVELOPMENT OF WDGBTM

Program WDGBTM was designed to perform four main functions. First, the pressure and phase along the interface of a wedge and underlying fast media may be calculated in two ways, for both infinitely and finitely distant sound sources in accordance with Ref. 5. Modifications were made to the code of Ref. 5 to facilitate subsequent in-bottom calculations, and to enhance user flexibility. These changes did not affect results. Then using the first code as input, additional code enables both the computation of pressure and phase along a line perpendicular to the wedge bottom, and as a function of radius and angle measured from the first mode dumping point, X.

Modes of program execution may be chosen by literal input directives combined with appropriate numerical input. Appendix A illustrates an input set that utilizes all four options. Output consists of both printed listings and graphics.

Program versions exist for execution on both a CDC 6500 and an IBM 360. The CDC 6500, with a 60 bit word, does not require double precision for accuracy equivalent to the IBM 360 output. The CDC version of WDGBTM has simpler varian control routines, and separate output files for each pressure/phase variation. This enables optional *suppression* of listings. Execution time on the CDC 6500 is roughly ten times faster than on the IBM 360. For average input sets, times are 150 and 1500 cp seconds respectively.

A. EQUATION PREPARATION

1. Depth Domain

Integrations along lines perpendicular to the wedge bottom were designated depth domain calculations. The program was designed to allow specification of the field point, i.e., specification of where along the media interface line the perpendicular probe line could be dropped. The field point is not confined to lines directly beneath the wedge, but may extend to points beyond the wedge apex. These points would be values of negative x in Figure II-1. The beginning and ending points of the section of the perpendicular to be examined, and the number of field points used in the interval were also to be specified.

Equation (II-9) was split into real and imaginary components before coding. Integration order selected was over the entire ξ' domain for each η point.

2. Angle Domain

Examination of Figure II-1 verifies the following geometric relationships.

$$\epsilon = \sigma \cos \theta_k \quad (\text{III-1a})$$

and

$$\eta = (\sigma^2 - \epsilon^2)^{1/2} \quad (\text{III-1b})$$

where ϵ is the distance from X to the ξ' coordinate of the field point of interest and σ is the radial distance from X to the field point.

Substitution of equations (III-1a) and (III-1b) into equation (II-9) yields

$$R(\vec{r}) = \frac{(\sigma^2 - \epsilon^2)^{1/2}}{4} \exp\left(\frac{i\pi}{4}\right) \left(\frac{2k_2 X}{\pi}\right)^{1/2} \int_0^\infty \frac{P(\xi') \exp\{i[L(\xi') - k_2 X[(\xi - \xi')^2 + \sigma^2 - \epsilon^2]^{1/2}]\} d\xi'}{[(\xi - \xi')^2 + \sigma^2 - \epsilon^2]^{3/4}} \quad (III-2)$$

Equation (III-2) is the basis for angle domain calculations. The specification of σ originating at X was chosen to conform to existing experimental data (Reference 8). The length of the radius, the beginning and ending of the angular sweep, and the angular increment comprise the input specifications. As in the depth domain option, equation (III-2) was split into real and imaginary components before coding.

3. Design Restrictions

Theoretical development of program WDGBTM assumes the sound source is sufficiently distant to ensure essentially locally planar waves at the interface and the in-bottom measurements satisfy the condition $k_2 |\vec{r} - \vec{r}'| \gg 2\pi$.

4. Program Results

An initial set of WDGBTM runs were made in the depth domain for a perpendicular directly down from the wedge apex. The source was infinitely distant and set at an angle of $\beta/2$. This limited modes within the wedge to odd numbered (symmetric) modes only. Integration over the wedge bottom was truncated at ξ equal four, so that only modes one and three were considered as contributing significantly to the beam pattern in the bottom. *Beam patterns in the bottom were calculated over the range η equal zero to $1.3X$.*

The initial set was comprised of seventy-five runs. In addition to the above criteria, the runs were generated by all possible combinations of the following specifications. The ration ρ_1/ρ_2 was 0.95, 0.90, 0.80, 0.70 or 0.50. The sound speed ratio, C_1/C_2 was set at 0.95, 0.90, or 0.85. The wedge angle β was varied through 10, 6.92, 5, 2 and 1 degree(s).

From the results of the initial data set, the depression angle and beam width was calculated for the beam pattern in the bottom. Results are summarized in Appendix B. These results were then used to find a simple analytical formula to predict the depression angle as discussed in Section IV.

Other runs were made for perpendiculars at $x = -9X$ from the wedge apex. These runs displayed apparent strong interference phenomona and are discussed in detail later.

Angle domain executions were made to compare with experimental data. Results are discussed in Section VII.

B. SENSITIVITY TO INTEGRATION STEP SIZE

It was desirable to keep both the integration step size and the field point increment size as large as possible in order to minimize total computer resources required. Increment of 0.01 times the dump distance (X) proved to be optimum for both integration increments along the wedge interface and field point steps in the bottom.

To illustrate the adequacy of 0.01X increment, a series of runs were made in accordance with Table III-1. An overlay of wedge interface pressure amplitude for $\Delta x = 0.01X$ and $\Delta x = 0.001X$ demonstrated no distinguishable difference. Likewise, depth domain plots (a, b, c, d of

Table (III - 1)

Sensitivity to Integration Step Size (Δx) and Field point interval size ($\Delta \eta$)

Run	$\eta_{\text{amp max}}$	θ_D
a	0.240	13.50
b	0.244	13.71
c	0.240	13.50
d	0.243	13.66

Table III-1) could be identically superimposed. Use of an integration step size of $0.001X$ resulted in a calculated depression angle within one percent of the depression angle for the $0.01X$ run. Utilization of a step size of greater than $0.01X$ is not recommended. Within this limitation the integrations can be carried out over $10X$ along the interface for a maximum field interval of $10X$ in the bottom. The $10X$ restriction is imposed by program array size. (For the σ 's specified, 0.5 degrees in the angle domain was slightly finer than the $0.01X$ field point step size in the depth domain and was the field point increment of choice).

IV. BEAM DEPRESSION ANGLE ANALYSIS

A simple relationship was sought between the physical parameters associated with the wedge system and the resultant beam.

Assume

$$\theta_{DC} \propto \beta^n \quad (\text{IV-1})$$

where θ_{DC} is the beam depression angle and β is the wedge angle. For each ρ_1/ρ_2 and C_1/C_2 , θ_{DC} vs β was graphed on log-log paper, and the slope (n) was measured. Results are listed in Table 1 of Appendix C, n equals 0.329.

Then θ_{DC} was found as a function of C_1/C_2 . The critical angle, θ_C , is an explicit function of C_1/C_2

$$\theta_C = \arccos (C_1/C_2) , \theta_C \text{ in radians} \quad (\text{IV-2})$$

It was then assumed

$$\theta_{DC} \propto \beta^{0.329} \theta_C^M \quad (\text{IV-3})$$

For any constant β , M was derived as the slope of a log-log graph of θ_{DC} vs θ_C . Graphs were analysed for β equal to 10, 6.92, 5, 2 and 1 degree, and ρ_1/ρ_2 ratios of 0.95, 0.90, 0.85, 0.70 and 0.50. Results are summarized in Table (2) of Appendix C, $M = 0.772$.

The same process was repeated for ascertaining dependence on ρ_1/ρ_2 . Log-log graphs were prepared by holding β and θ_C constant using the assumed relation

$$\theta_{DC} \propto \beta^{0.329} \theta_C^{0.772} (\rho_1/\rho_2)^q \quad (\text{IV-4})$$

Results are summarized in Table 3 of Appendix C. $q = -0.254$.

The proposed formula is now dependent on all physical properties, assuming the source angle is maintained at one-half β . To remove the proportionality sign, write

$$\theta_{DC} = K \beta^{0.329} \theta_C^{0.772} (\rho_1/\rho_2)^{-0.254} \quad (\text{IV-5})$$

and solve for K . From Table 4, Appendix C, $K = 17.22/\text{radian}$.

Therefore

$$\theta_{DC} = 17.22 \beta^{0.329} \theta_C^{0.772} (\rho_1/\rho_2)^{-0.254} \quad (\text{IV-6})$$

where β is in degrees and θ_C in radians.

θ_{DC} calculated from equation (IV-6) and the difference between θ_{DC} and θ_D from program WDGBTM (labeled $\Delta\theta_D$ and θ_{DW} respectively) are also tabulated on Table 4, Appendix C. $\Delta\theta_D$ varies from a minimum of 0.00 to a maximum of 1.25, with the average of the absolute values of $\Delta\theta_D$ equal to 0.36. Errors ranged from zero percent to 5.0 percent. Thus θ_{DC} gives a reasonable approximation of the beam depression angle.

A similar formula

$$\theta_{DA} = 17.1 \beta^{1/3} \theta_C^{0.773} (\rho_1/\rho_2)^{-0.27} \quad (IV-7)$$

was developed independently by A. Coppens (Reference 6) The minimum deviation of θ_{DA} from θ_{DW} is 0.01 and the maximum deviation is 1.56. The average of the absolute value of the deviation is 0.36. Both formulas are best for ρ_1/ρ_2 close to 1.0, and less accurate for ρ_1/ρ_2 equal to 0.5.

V. THE EFFECT OF ATTENUATION

As previewed in Section III-A.4 the pressure distribution as a function of η at $x = -9.0X$ demonstrated apparent interference effects (see figure V-1). As integration over the wedge interface to $4X$ encompasses dumping by the first and third mode, and the third mode dumps about the point $3X$ vice X for the first mode, it is logical to expect attenuation effects to reduce the contribution of the more distant mode. The initial Green's function approach, equation (II-9) did not consider attenuation of the acoustic wave in the bottom medium. An attenuation term

$$\exp \{-\alpha [(\xi - \xi')^2 + \eta^2]^{1/2}\} \quad (V-1)$$

was incorporated into equation (II-9) to yield

$$R(\vec{r}) = \eta/4 \exp\left(\frac{i\pi}{4}\right) \left(\frac{2k_2X}{\pi}\right)^{1/2} \quad (V-2)$$

$$\int_0^{\infty} \frac{\bar{P}(\xi') \exp\{-\alpha [(\xi - \xi')^2 + \eta^2]^{1/2}\} \exp\{i[L(\xi') - k_2X [(\xi - \xi')^2 + \eta^2]^{1/2}]\} d\xi'}{[(\xi - \xi')^2 + \eta^2]^{3/4}}$$

An appropriate code modification to the depth domain routine was made.

The attenuation coefficient α was an input variable to the program.

Two sets of comparison runs were made. The first set consisted of an unattenuated control ($\alpha = 0$) and an attenuated run with α equal 1.0, with the pressure amplitude measured down from the wedge apex. The second set consisted of an unattenuated control plus runs with α set to 1.0, 0.5, 0.1, and 0.01 and the pressure measured at $x = -9.0$ from the

apex. All other input variables for both sets were held constant and are specified in Table (V-1). Integration over the wedge bottom was from the apex to four times the dump distance; this was to insure that contributions from the third mode (dumping about the point $x = 3X$) were included.

The results of set one are illustrated in Figure (V-2). Note that the second maxima is severely depressed in the attenuated case. The depression angle has been shifted slightly from 11.86 degrees for the unattenuated data to 11.31 degrees with α set to 1.0.

Figure V-3 is a plot of the results from set two. All curves have been normalized to the initial slope for $\alpha = 1.0$. The second and third maxima decrease with increasing α , and relatively more energy is contained in the first beam. The depression angle of the first beam decreases slightly with increasing α . These trends are summarized in Table (V-2).

Figures (V-4a) and (V-4b) illustrate the effects of attenuation on different contributing modes. For Figure (V-4a), the source was placed at $1/3 \beta$. With this source geometry, contributions from mode three are suppressed, and only the first and second mode contributed to the beam pattern in the bottom. For Figure (V-4b), the source was placed at $1/2 \beta$ and modes one and three propagate into the bottom medium. Both cases were run for $\alpha = 1.0, 0.5, 0.1$ and 0.0 . As could be expected, attenuation causes greater suppression of third mode interference contributions than of second mode contributions.

VI. ANALYSES OF FAR-FIELD INTERFERENCE PATTERNS

The results of the attenuation investigation were supportive of an interference explanation for the multiple beams. Subsequently, two analytical approaches were tried to predict the location of interference maxima and minima under unattenuated far-field conditions.

Both the Differential Change and Multiple Lambda analyses assume very simple processes. Both assume point sources of sound at the wedge interface located at X and $3X$. Realistically the sound sources behave as phased arrays propagating asymmetrically about the dumping points. Phase differences between the two dumping points are non-zero. The Differential Change formula becomes invalid as η approaches zero.

A. DIFFERENTIAL CHANGE APPROACH

Based on the simple geometric considerations illustrated in Fig (VI-1), the following nondimensional formula for the change in interference maxima locations was derived.

$$\Delta\eta = \frac{4 (C_2/C_1) \sin \theta_C \sin \beta}{\left\{ \frac{\eta}{[\eta^2 + (1-X)^2]^{1/2}} - \frac{\eta}{[\eta^2 + (3-X)^2]^{1/2}} \right\}} \quad (\text{VI-1})$$

Note that equation (VI-1) is dependent only on the wedge angle β and the sound speeds of the two fluid media.

A series of WDGTM executions were made for varying C_2/C_1 and β , with all other variables held constant. Table (VI-1) is a summary of one case, this case is typical of results observed. Results will be discussed in Section VI-C.

Figure (VI-1)

TABLE VI-1

Comparison of $\Delta\eta$ from equation (VI-1) and $\Delta\eta$ from WDGBTM results.

$$C_1/C_2 = 0.90$$

β	WDGBTM maxima locations	$\Delta\eta$ from WDGBTM	$\Delta\eta$ predicted
5.0	2.38	1.67	4.56
	4.05	1.92	3.04
	5.97		
2.5	2.33	1.40	2.33

	4.75	0.91	1.38
	5.66		
1.25	2.08	1.22	1.29
	3.30	0.66	0.88
	3.96	0.49	0.77
	4.45		

B. MULTIPLE LAMBDA APPROACH

The second interference pattern calculation also utilizes the geometry of Fig. (VI-1). For each C_1/C_2 ratio and beta combination, X and λ_2 (the wavelength in the bottom media) was calculated according to the equations

$$X = \frac{C_1}{4f \sin \theta_C \sin \beta} \quad (\text{VI-2})$$

and

$$\lambda_2 = C_2/f \quad (\text{VI-3})$$

where f is 150khz. The ratio $\lambda_2/X = Q$ is then found and used in the relation

$$NQ = [\eta^2 + (3-X)^2]^{1/2} - [\eta^2 + (1-X)^2]^{1/2} \quad (\text{VI-4})$$

where N is any positive integer. Note that use of equation (VI-4) assumes zero initial phase.

To find the expected maxima and minima, a plot of η vs N was made for each Q . Maxima are expected for each integer N , minima for each $N + 1/2$. Table (VI-2) summarizes one case of maxima and minima expected as a result of equation (VI-4) versus maxima and minima observed on WDGBTM output.

C. SUMMARY OF ANALYSES

Predictions from both simple analyses are of the same order of magnitude as WDGBTM results. The number of maxima and minima are

TABLE VI-2

OCCURRENCE OF MAXIMA AND MINIMA

$$C_1/C_2 = 0.85$$

β (DEG)	η MAX WDGBTM	η MAX EXP	η MIN WDGBTM	η MIN EXP
5	4.03	2.68 6.34	5.39	4.70
2.5	3.59 5.00	2.59 4.70	4.55 5.66	3.76 5.56
1.25	2.02 2.85 3.81 5.03 5.62	2.53 3.72 4.68 5.54	2.49 3.56 4.77 5.40 5.90	1.76 3.16 4.25 5.13 5.94

consistently predicted as increasing with decreasing wedge angle. Occasional unexplainable phenomena, such as increasing WDGBTM $\Delta\eta$ for the $\beta = 5$ on Table (VI-1) and the extra WDGBTM maxima for $\beta = 5$ Table (VI-2), were observed, but results are generally supportive of an interference effect *occurring*.

VII. COMPARISONS

A. EXPERIMENTAL DATA

Netzorg (Reference 4) measured pressure amplitude as a function of angle for fixed radii in four media below a wedge shaped upper layer. The angle domain version of WDGBTM was used to compare calculated pressure patterns with measured patterns.

All runs utilized finite source input. For each of Netzorg's four experimental cases, corresponding computer runs were made with the source distance set to 100X, 10X and SX, where S corresponds to the actual source distance used in the tank. In all cases S was less than 10X. The integrations were carried out over one dumping distance and four dumping distances for each source.

Figure (VII-1) is typical of pressure amplitudes in the bottom. The source in the experiment was only *about* 40 wavelengths from the dumping point, even at 10X the source is approximately 110 wavelengths away. Since the method of images calculations utilized to determine the pressure amplitude along the wedge bottom assume a plane wave, it is questionable that this program can produce a realistic comparison with the measured data.

Figures (VII-2) and (VII-3) illustrate the wide variation in results obtained depending on the source distance and integration interval. Calculations demonstrate expected trends, i.e., pressure amplitude increases with decreasing radius distance (σ), with closing source

distance, and as a function of an increasing integration interval over the wedge bottom. The beam depression angle becomes more shallow as source distance increases. Results at very low angles are not considered valid because of assumptions inherent in the WDGBTM model.

The circled data points of Figures (VII-2) and (VII-3) are a transposition of data from Reference 4. Since absolute amplitude was not specified in the reference, rescaling to the case most near to the actual conditions was performed, i.e., the data were normalized to the case $X_2 = 1.0$ and $srcd = 3.5X$. The shape of the experimental curve and the apparent beam depression angle are the only valid comparisons that should be made.

Comparisons of WDGBTM beam depression angles with measured values gave varying results. Measured depression angles decreased with increasing σ , WDGBTM depression angles increased. WDGBTM results were within 6 percent to 62 percent of measured values. No correlation was observed between prediction accuracy and source distance or prediction accuracy and the interface integration interval. All measured beam depression angles in Reference 8 were for the two shortest radii of each case, the three longer radii could only be qualitatively compared with graphical data. Possible attenuation effects were not considered. Numerical results are contained in Appendix D.

B. PARABOLIC EQUATION APPROACH

Kuperman (Reference 9) describes a Parabolic Equation model result for a wedge problem, and compares these results to one set of data extracted from Reference 10.

The Parabolic Equation results show very well defined beams in the bottom, with no apparent interference effects as observed in comparable WDGBTM runs (Figures V-1 and V-4). Kuperman used an attenuation factor of 0.5dB per wave length, a value equivalent to an input of 0.984 Nepers/X for WDGBTM. It should be noted in Figure V-4 that there is complete separation of the beams for WDGBTM when $\alpha = 1.0$.

Kuperman states agreement within 20 percent of a measured data set of Reference 10. This measured data is identical to Case 1 of Appendix D. WDGBTM accuracy for this case varied from zero percent error to 22 percent error with error calculated according to the formula

$$100 \times \frac{(\text{observed data}) - (\text{measured data})}{\text{measured data}}$$

VIII. CONCLUSIONS

1. Program WDGBTM offers a fast, efficient means of analysing the behavior of sound in a fast bottom underlying a wedge-shaped medium. Effects of attenuation are easily demonstrated, and modes desired are readily controlled by specification of source location and integration interval selected. Results of the model are not inconsistent with current measured data, and illuminate observations generated by the Parabolic Equation model.

2. A simple equation for calculating beam depression angle as a function of wedge characteristics was obtained which offers sufficient accuracy for use as a rapid analytical tool. The equation was derived for acoustic sources placed at one-half the wedge angle. Accuracy degrades when the wedge medium density to bottom medium density ratio decreases to 0.5.

3. It is recommended that further experiments be performed that would further test the model. New experiments should be sufficiently large scale to ensure plane waves at the wedge bottom interface and to satisfy the $k_2 |\vec{r} - \vec{r}'| \gg 2\pi$ criteria. Bottom media that reasonably model real ocean fluid-like bottom are also recommended.

WDGBTM

PROGRAM WDGBTM USES THE METHOD OF IMAGES WITH EITHER AN INFINITELY DISTANT OR FINITE DISTANCE SOURCE TO CALCULATE THE PRESSURE AND PHASE ALONG THE BOTTOM OF A WEDGE LAYING OVER A FAST BOTTOM. THE PRESSURE AND PHASE ARE OUTPUT BEFORE IN BOTTOM CALCULATIONS ARE BEGUN. THE PRESSURE AND PHASE ALONG THE WEDGE BOTTOM ARE THEN USED TO CALCULATE PRESSURE AND PHASE IN THE BOTTOM AS A FUNCTION OF DEPTH FROM THE WEDGE BOTTOM OR AS A FUNCTION OF ANGLE AND RADIUS FROM THE FIRST MODE DUMPING POINT. THE OUTPUTS ARE RESPECTIVELY REFERRED TO AS THE DEPTH DOMAIN AND ANGLE DOMAIN. ALL DIMENSIONS ARE NORMALIZED TO THE DUMP DISTANCE CAPX. ALL Q VARIABLES ARE SINGLE PRECISION VALUES TO FEED PLOT ROUTINES.

ALL CALCULATIONS FOR PRESSURE AND AMPLITUDE ALONG THE WEDGE BOTTOM ARE AN ADAPTION OF PROGRAMS BY KAWAMURA (PRESSURE ON THE INTERFACE BETWEEN A CONVERGING FLUID WEDGE AND A FAST FLUID BOTTOM, KAWAMURA, M., AND IOANNOU, M.S. THESIS, NAVAL POSTGRADUATE SCHOOL, MONTEREY, 1978).
